The term "carbohydrates" describes a major group of naturally occurring compounds of widely varying molecular masses. The low molecular mass carbohydrates comprise a family of more or less sweet-tasting, water-soluble, colorless products with physical, chemical, and physiological properties. They are often generically called "sugars," which is the familiar sucrose.

The high molecular mass carbohydrates are called polysaccharides. Their properties differ significantly from those of the low molecular mass carbohydrates. They do not taste sweet and are not soluble in water.

All carbohydrates are composed of units of monosaccharides or their derivatives. Carbohydrates are usually classified by the number of monosaccharide units in their molecules. A monosaccharide contains an uninterrupted chain of a limited number (five or six) of carbon atoms. In disaccharides, trisaccharides, tetrasaccharides, etc., and in polysaccharides, the monosaccharides are linked together through glycosidic oxygen atoms.

Oligosaccharides are considered to be low molecular mass carbohydrates. However, no definite borderline between oligosaccharides and the polysaccharides exists. In general, naturally occurring oligosaccharides are rarely con-

sist of more than 5, and polysaccharides of less than 100, monosaccharide units.

Most monosaccharides, oligosaccharides, and polysaccharides have the common molecular formula $C_n(H_2O)_n$ (from which the common name "carbohydrates" is derived), in which n is either equal to m (monosaccharides) or a little larger than m (oligo- and polysaccharides). Oligomers are formed by condensation (formal elimination of water) of monosaccharide units, and conversely oligo- and polysaccharides can be degraded to monosaccharides by hydrolysis. The whole biomass on earth has been estimated to be about 90% carbohydrates, which means that the molecular formula of the total organic matter on earth is only slightly different from that of the carbohydrates.

Carbohydrates have important functions: primarily they supply chemical energy to the living cell and serve as raw materials for the construction of other natural products. Carbohydrates are mainly formed in the photochemical carbon dioxide fixation in green plants, a complicated biochemical process which provides for the efficient conversion of solar energy into chemical energy. The uses of carbohydrates for the supply of primary energy and as raw materials in synthetic organic chemistry represent an important facet of present and future technology.

Carbohydrates are industrially utilized to a considerable extent. Glucose [50-99-7] is the

starting material for the production of ascorbic acid. Maltose [69-7] the enzymatic degradation of starch, can be reduced to maltitol, which is used as a sweetener. A similar sweetener (sorbitol) [64519-83-0], a mixture of alcohols *O*- α -D-glucopyranosyl-*D*-mannitol [20942-99-5] and *O*- α -(1 \rightarrow 6)-*D*-glucitol [134-73-0], obtained by reduction of isomaltulose (palestinose) [13718-94-0], a product of enzymatic isomerization of sucrose. Fructose [57-4] itself is used as a sweetener by diabetics.

Many nonionic detergents are derived from carbohydrates. Used in soap, they are less irritating than their alkali counterparts and can easily be degraded, therefore causing no environmental problems. Polysaccharides are produced and used in a wide variety of applications. These include substitutes for blood serum (dextran), and starch bases), wrapping (phases), additives to food and pharmaceuticals and cosmetics (starches, plant and microbial fluids in oil fields. Cellulose is or cotton is one of the most important raw materials.

Production. Natural carbohydrates are obtained exclusively from biological sources. Total synthesis is impractical, as 3-epimerization of *D*-glucose to *D*-mannose, which is tedious. Chemical synthesis of oligosaccharides by coupling suitable monosaccharides are extremely difficult and the chemical synthesis of a polysaccharide is almost impossible. One possibility is the polymerization of polyhydroxy sugar derivatives, which yields polyhydroxy pyranans.

1. Monosaccharides

Monosaccharides are polyhydroxy aldehydes (*oses*, aldoses) or polyhydroxy ketones (*uloses*, ketoses). The carbon skeleton in most monosaccharides is linear (n most all ketones the carbonyl carbon atom 2. Most monosaccharides have either six (hexoses and hexuloses)

Cellulose is or cotton is one of the most important raw materials.

Production. Natural carbohydrates are obtained exclusively from biological sources. Total synthesis is impractical, as 3-epimerization of *D*-glucose to *D*-mannose, which is tedious. Chemical synthesis of oligosaccharides by coupling suitable monosaccharides are extremely difficult and the chemical synthesis of a polysaccharide is almost impossible. One possibility is the polymerization of polyhydroxy sugar derivatives, which yields polyhydroxy pyranans.

Monosaccharides are polyhydroxy aldehydes (*oses*, aldoses) or polyhydroxy ketones (*uloses*, ketoses). The carbon skeleton in most monosaccharides is linear (n most all ketones the carbonyl carbon atom 2. Most monosaccharides have either six (hexoses and hexuloses)

and pentuloses) carbon atoms. Monosaccharides with fewer carbon atoms (trioses, tetroses, and pentoses) or more carbon atoms (heptoses, octoses, heptuloses, octuloses, etc.) are rare. The most important and abundant monosaccharides are hexoses: *D*-glucose, *D*-mannose, and *D*-galactose. *D*-Fructose is a hexulose. Ubiquitous pentoses are *L*-arabinose, *D*-xylose, and *D*-ribose.

Stereoisomerism. Monosaccharides (as polyhydroxy aldehydes or ketones) possess several asymmetric carbon atoms. Hexoses have four, hexuloses and pentoses three, and pentuloses two chirality centers. The existence of several asymmetric carbon atoms in one molecule gives rise to families of stereoisomers. For a hexose with four asymmetric carbon atoms, there exist 2⁴ stereoisomers, eight of which are enantiomers (mirror images) of the other eight. Hexuloses exist in four pairs of enantiomers, pentuloses and tetroses in two. The diastereomeric monosaccharides (diastereomers are stereoisomers that are not mirror images of each other) have trivial names. In Figure 1, *D*-hexoses, *D*-hexuloses, *D*-pentoses, and *D*-tetroses are represented as open-chain Fischer projections. In the Fischer projection all carbon atoms form a bow with the convex part pointing toward the viewer. According to the Fischer convention, the orientation of the hydroxyl group attached to the highest numbered asymmetric carbon atom determines whether a monosaccharide belongs to the *D*- or the *L*-series. If this group is positioned on the right of the carbon chain, assignment is to the *D*-series, and vice versa. Most naturally occurring monosaccharides have the *D*-configuration. The chirality of carbohydrates makes this class of natural compounds an ideal source for the preparation of chiral synthons (intermediates for chemical synthesis), which are needed for the synthesis of pharmaceuticals, agrochemicals, pheromones, etc. [26], [27].

Pyranoses and Furanoses. Monosaccharides form cyclic intramolecular hemiacetals if their carbon skeleton permits. The relative stabilities of these hemiacetals depend on the ring size. In general, six-membered rings (pyranoses) are most common, whereas only a few five-membered rings (furanoses) are stable. Smaller rings are unstable, and larger ones can only be detected in aqueous equilibrium mixtures. Structures of the cyclic hemiacetals are represented by the Haworth projection formulas of the *D*-series

1. Cellulose

Cellulose [9004-34-6] deserves a special position among the industrially used raw materials for two general reasons. First, as to the natural products which, fully, are inexhaustible since it is generated by nature in relatively short time periods. As long as we ensure that the primary sources of cellulose, forests and cotton plantations, are not damaged by destructive lumbering, we can expect regular and sufficient annual reproduction.

According to references [8], if cellulose matter resulting from

a special position among the industrially used raw materials for two general reasons. First, as to the natural products which, fully, are inexhaustible since it is generated by nature in relatively short time periods. As long as we ensure that the primary sources of cellulose, forests and cotton plantations, are not damaged by destructive lumbering, we can expect regular and sufficient annual reproduction.

biosynthesis amounts to approximately 1.3×10^9 metric tons. A tree produces an average of 13.7 g of cellulose daily. If they were lined up, the cellulose chain molecules formed each day would result in a string of 2.62×10^{10} km in length, or 175 times the distance between the sun and the earth.

In wood, cellulose is part of an ingeniously constructed fiber-reinforced composite in which long, stiff cellulose chain molecules organized in thin fibrils constitute the plant skeleton material held together and protected by hydrophobic lignin acting as binder and encasement.

To isolate cellulose from wood for industrial applications, the wooden composite must be broken up by so-called pulping processes. In

glucose base unit is $m_0 = 162$, and the molecular mass of the cellulose polymer is

$$M_n = m_0 P + 18 = 162 P.$$

Constitutional Formula. HAWORTH [10] first discovered the covalent bonds inside and between the glucose units while STAUDINGER [11] found the final proof for the macromolecular nature of the cellulose molecule.

Conformational Formula. The glucopyranosic ring adopts a 4_1 chair conformation, as revealed by recent X-ray crystallography and nuclear magnetic resonance studies [12], [13] with glucose. The chair formation in comparison to the tray conformation exhibits a free stabilization enthalpy of $G_s = 20.05$ kJ/mol [14]. In this conformation, the three hydroxyl groups are positioned in the ring plane while the hydrogen atoms are in a vertical position. It seems only natural to assume that the same conformation also exists in the cellulose molecule.

1.1. Properties

1.1.1. Molecular Structure

Cellulose is an insoluble β -1,4-polyacetal of cellobiose (4-O- β -D-glucopyranosyl-D-glucose). The actual base unit, cellobiose, consists of two molecules of glucose can also be considered as a (syndiotactic) polyacetal of glucose.

Basic Structure. The basic chemical formula of cellulose is the following:

$$C_6H_{10-2P}O_{5-P} = (C_6H_8O_5)_P \quad \text{or} \quad (C_6H_{10}O_5)_n$$

where P = the degree of polymerization; n = the number of units in the chain.

The elemental composition of cellulose was already known to PAYEN in 1842 [9]. The

basic chemical formula is:

position of 44.4% C, 6.2% H, and 49.4% O was already known to PAYEN in 1842 [9]. The molecular mass of the

Structural Anomalies. As a naturally occurring polymer, cellulose always contains small amounts of other constituents in addition to glucose (over 99%). These may already be partially built into or onto the cellulose molecules during biosynthesis, such as lignin-cellulose complexes [15]. Most of the changes in the molecular structure, however, result from secondary reactions, i.e., hydrolysis or oxidation, during isolation from natural sources. For morphological reasons, such chemical changes occur preferably in

Cellulose 377

the accessible interlinking regions of the elementary fibrillar aggregations. The glucosidic linkages, especially if oxidized, can split 1000–3000 times faster than glucosidic linkages inside the well-ordered crystallites. The existence of weak links, as proposed in reference to hydrogen bonds, is hard to determine. In the hydrolysis, all glucosidic linkages split at the same rate [17].

Cellulose always contains carboxylic groups: in wood pulp, one –COOH group per 100–1000 anhydroglucose units (AHG); in cotton, one –COOH group per 100–300 AHG units.

Molecular Size. The molecular size can be defined by its average molecular weight (\bar{M}_n) or its average degree of polymerization (\bar{P}_n), where $\bar{M}_n = \bar{P}_n m_0$ (m_0 = molecular weight of glucose in the chain, i.e., of glucose in the chain).

By investigation of certain physical properties of cellulose or polymeric cellulose derivatives in solution, the average degree of polymerization can be determined. The number average degree of polymerization of cellulose of various

For such physical investigations in aqueous copper(II) hydroxide (Schweizer's reagent), copper(II) ethylenediamine hydroxide, alkaline solutions of the ethylenediamine complexes of cadmium or nickel. Cellulose trinitrate (CTN) or cellulose tricarboxylate (CTC) solutions in appropriate solvents are also suitable for such studies. In the latter, it should be kept in mind that chain degradation often occurs in reactions performed under unfavorable

conditions or their aggregates. These accessible linkages are also present in the crystallites. The linkages inside the well-ordered crystallites. The existence of weak links, as proposed in reference to hydrogen bonds, is hard to determine. In the hydrolysis, all glucosidic linkages split at the same rate [17].

size of a polymerization (\bar{P}_n); molecular mass of the cellulose. The physical properties of cellulose derivatives in solution, the average degree of polymerization can be determined. The number average degree of polymerization of cellulose of various

Light scattering studies performed on dilute solutions of cellulose or cellulose derivatives will yield the weight average (\bar{M}_w) and osmotic measurements the number average (\bar{M}_n) of the molecular mass (or the corresponding average degrees of polymerization: \bar{P}_w or \bar{P}_n). Sedimentation experiments in an ultracentrifuge enable the determination of a higher order average molecular mass, the so-called "Z-average" (\bar{M}_z). These various quantities are defined as follows:

$$\bar{M}_w = \frac{\sum N_i \cdot M_i^2}{\sum N_i \cdot M_i} \quad \text{or} \quad \bar{P}_w = \frac{\sum N_i \cdot P_i^2}{\sum N_i \cdot P_i} \quad (\text{weight average})$$

$$\bar{M}_n = \frac{\sum N_i \cdot M_i}{\sum N_i} \quad \text{or} \quad \bar{P}_n = \frac{\sum N_i \cdot P_i}{\sum N_i} \quad (\text{number average})$$

$$\bar{M}_z = \frac{\sum N_i \cdot M_i^3}{\sum N_i \cdot M_i^2} \quad \text{or} \quad \bar{P}_z = \frac{\sum N_i \cdot P_i^3}{\sum N_i \cdot P_i^2} \quad (\text{Z-average}).$$

whereby $N_i = 10^3 P_i$ (fraction 1, 2, 3, ..., N = number of molecules with M_1, M_2, \dots, M_N or P_1, P_2, \dots, P_N).

The simplest and most widely applied practical method for the determination of the degree of polymerization is based on measuring the "intrinsic viscosity η " (Staudinger index). The intrinsic viscosity expresses the reduced viscosity of a solution at an infinitely small concentration. The latter can be derived from the relative viscosity, which is the ratio of the flow time of the dilute polymer solution of a given concentration (t_p) and that of the solvent (t_s) in a capillary viscometer:

$$\eta_{sp} = \frac{t_p - t_s}{t_s} \cdot \frac{1}{c}$$

whereas c = concentration of the cellulose or its derivative in the solution.

The degree of polymerization can be calculated from $[\eta]$ by using the formula:

$$[\eta] = \lim_{c \rightarrow 0} \frac{\eta_{sp}}{c} = K_1 \bar{P}_n^a \quad (\text{or } K_2 \bar{M}_n^b)$$

The definition of \bar{P}_n (viscosity average of the degree of polymerization) is as follows:

$$\bar{P}_n = \left(\frac{\sum w_i P_i^a}{\sum w_i} \right)^{1/a}$$

wherein w_i = weight fraction of a molecularly uniform fraction with a degree of polymerization of P_i ; \bar{P}_n = viscosity average of the degree of polymerization which for cellulose or cellulose derivative solutions closely resembles the weight average \bar{P}_w ; and \bar{M}_n = viscosity average of the molecular mass.

Table 1. Degree of polymerization of cellulose of different origin [18]

Type of cellulose	\bar{P}_n
Cotton, raw	7000
Cotton, raw (according to Russian work)	14000
Cotton, purified	1500–3000
Cotton linters	6500
Flax	1000
Ramie	6500
α -Cellulose (isolated from wood fibers)	1100–800
Spruce, pulped	3300
Beech, pulped	3050
Aspen	2500
Fir	2500
Bacterial cellulose	2700
Acetobacter cellulose	600
